Abstract

Discrete values have important roles in data mining and knowledge discovery. Many studies have shown that induction tasks can benefit from discretization: rules with discrete values are normally shorter and hence easier to understandable and discretization can lead to improved predictive accuracy. Furthermore, many induction algorithms found in the literature require discrete features. All these prompt researchers and practitioners to discretize continuous features before or during a machine learning or data mining task. There are numerous discretization methods reported in the literature. This paper aims at a systematic study of these different discretization methods to examine their history of development, effects on classification, and trade-off between speed and accuracy. Comparative experiments among various methods are given and an analysis of the results is provided in the paper. Contributions of this paper are an abstract description summarizing existing discretization methods, a hierarchical framework to categorize the existing methods and pave the way for further development, concise discussions of representative discretization methods for classification, extensive experiments and their analysis, and some guidelines as to how to choose a discretization method under various circumstances. Finally, the paper also identifies several unsolved issues and future research for discretization.

Keywords: *Discretization, Continuous Feature, Data Mining, Classification.*

1 Introduction

Data usually comes in a mixed format: nominal, discrete, and/or continuous. Discrete and continuous data are ordinal data types having orders among the values, while nominal values do not possess any order amongst them. Discrete data are spaced out with intervals in a continuous spectrum of

values. While the number of continuous values for an attribute can be infinitely large, the number of discrete values is often few or finite. These two types of values make a difference in learning classification trees/rules. One example of decision tree induction can further illustrate the difference between the two data types. When a decision tree is induced, handling continuous values makes the induction process more complicated than using discretized values. There is a need to discretize continuous features either before the decision tree induction or during the process of tree building [22]. Widely used systems such as C4.5 [25] and CART [2] deploy various ways to avoid using continuous values directly. Binarization of a continuous feature is one way of doing so [5]. Recent work by Elomaa and Rousu [10] provides a general and efficient approach to multi-splitting of numerical features during the process of tree building. There are many other advantages of using discrete values over continuous ones. Data can also be reduced and simplified through discretization. For both users and experts, discrete features are easier to understand, use, and explain. As reported in a study [9], discretization makes learning more accurate and faster. In general, results (e.g., decision trees, induction rules) obtained using discrete features are usually more compact, shorter and more accurate than using continuous ones, hence the results can be more closely examined, compared, used and reused. In addition to many advantages of having discrete data over continuous one, a suite of classification learning algorithms can only deal with discrete data. Discretization is a process of quantizing continuous attributes. The success of discretization can significantly extend the borders of many learning algorithms.

This paper reviews existing discretization methods, standardizes the discretization process, summarizes them with an abstract framework, and provides a convenient reference for future research and development. The remainder of the paper is organized as follows. In the next section, we summarize the current status of discretization methods with an emphasis on discretization in a preprocessing phase. In Section 3, we provide a unified vocabulary for discussing various methods introduced by many authors, define a general process of discretization, and consider different ways of evaluating discretization results. In Section 4, we propose a new hierarchical framework for discretization methods and describe representative methods concisely. While describing each representative method, we also provide its discretization results for a benchmark data set (Iris). It is a small data set, commonly used in discretization and classification works [32], and employed here to illustrate the working procedures of different algorithms. Section 5 shows the results of comparative experiments among various methods and an analysis of the results. The paper concludes in Section 6 with guidelines of choosing a discretization method and further work.

2 Current Status

In earlier days simple techniques were used such as equal-width and equal-frequency (or, a form of binning) to discretize. As the need for accurate and efficient classification grew, the technology for discretization develops rapidly. Over the years, many discretization algorithms have been proposed and tested to show that discretization has the potential to reduce the amount of data while retaining or even improving predictive accuracy. In general, discretization methods have been developed along different lines to meet different needs: supervised *vs.* unsupervised, dynamic *vs.* static, global *vs.* local, splitting (top-down) *vs.* merging (bottom-up), and direct *vs.* incremental.

Discretization can be **supervised** or **unsupervised** depending on whether a discretization method exploits class information while discretizing the data. Supervised discretization uses class information to guide the discretization process; while unsupervised discretization does not. Discretization without class information is seen in earlier methods like equal-width and equal-frequency: continuous ranges are divided into subranges by the user given pre-specified width (range of values) or frequency (number of instances in each interval).

This may not give good results in cases where the distribution of the continuous values is not uniform. Furthermore it is vulnerable to outliers as they affect the ranges significantly [3]. To overcome this shortcoming, supervised discretization methods were introduced and class information is used to find the proper intervals defined by cut-points. Different methods have been devised to use this class information for finding meaningful intervals in continuous attributes. If no class information is available, unsupervised discretization is the sole choice. There are not many unsupervised discretization methods reported in the literature which may be attributed to the fact that discretization is commonly associated with the classification task.

The usage of discretization methods can be **dynamic** or **static**. A dynamic method would discretize continuous values when a classifier is being built, such as in C4.5 [25] while static discretization is done prior to the classification task. There is a comparison between dynamic and static methods in [9]. The authors reported mixed performance when C4.5 was tested with and without discretized features (static *vs.* dynamic).

Another dichotomy is **local** *vs.* **global**. A local method would discretize in a localized region of the instance space (i.e., a subset of instances) while a global discretization method uses the entire instance space to discretize [7]. A local method is usually associated with a dynamic discretization method in which only a region of instance space is used for discretization.

Discretization methods can also be grouped in terms of **top-down** or **bottom-up**. Top-down methods start with an empty list of cut-points (or split-points) and keep on adding new ones to the list by 'splitting' intervals as the discretization progresses. Bottom-up methods start with the complete list of all the continuous values of the feature as cut-points and gradually remove some of

them by 'merging' intervals as the discretization progresses.

Another dimension of discretization methods is **direct** *vs.* **incremental**. Direct methods divide the range of k intervals simultaneously (i.e., equal-width, equal-frequency, or K-means), needing an additional input from the user to determine the number of intervals. Incremental methods begin with simple discretization and are followed by an improvement or refinement process, which requires a stopping criterion to halt further discretizing [4].

As shown above, there are numerous discretization methods and many different dimensions to group them. A user of discretization often finds it difficult to choose a suitable method for the data at hand. There have been a few attempts [9, 4] to help alleviate the difficulty. We carry on with this key objective to make a comprehensive study that includes the definition of a discretization process, performance measures, and extensive comparison. Contributions of this work are:

1. An abstract description of a typical discretization process,
2. A new hierarchical framework to categorize existing discretization methods in the literature,
3. A systematic demonstration of different results by various discretization methods using a benchmark data set,
4. A comparison of nine representative discretization methods chosen from the framework along two dimensions: time taken and error rates of a learning algorithm for classification over publicly available benchmark data sets,
5. Detailed examination of comparative results, and
6. Some guidelines as to which method to use under different circumstances, and directions for future research and development.

3 Discretization Process

We first clarify several terms used in different works followed by an abstract description of a typical discretization process.

3.1 Terms and Notations

Feature: A "feature" or "attribute" or "variable" refers to an aspect of the data. Usually before collecting data, features are specified or chosen. Features can be discrete, continuous, or nominal. In this paper we are interested in the process of discretizing continuous features. Hereafter M stands for the number of features in the data.

Instance: An "instance" or "tuple" or "record" or "data point" refers to a single collection of feature values for all features. A set of instances makes a data set. Usually a data set is in a

matrix form where each row corresponds to an instance and each column corresponds to a feature. Hereafter N is the number of instances in the data.

Cut-Point: The term "cut-point" refers to a real value within the range of continuous values that divides the range into two intervals. One interval is less than or equal to the cut-point and the other interval is greater than the cut-point. For example, a continuous interval $[a, b]$ is partitioned into $[a, c]$ and $(c, b]$, where the value c is a cut-point. Cut-point is also known as split-point.

Arity: The term "arity" in the discretization context means the number of intervals or partitions. Before discretization of a continuous feature, arity can be set to k - the number of partitions in the continuous features. The maximum number of cut-points is $k - 1$. Discretization process reduces the arity but there is a trade-off between arity and its effect on the accuracy of classification and other tasks. A too high arity can make the learning process longer while a very low arity may affect the predictive accuracy negatively.

3.2 A Typical Discretization Process

By "typical" we mean *univariate* discretization. Discretization can be univariate or multivariate. Univariate discretization quantifies one continuous feature at a time while multivariate discretization considers simultaneously multiple features. We mainly consider univariate discretization throughout this paper and briefly discuss multivariate discretization at the end of this paper as an extension to the univariate discretization.

A typical discretization process broadly consists of four steps (seen in Figure 1): (1) *sort* the continuous values of the feature to be discretized, (2) *evaluate* a cut-point for splitting or adjacent intervals for merging, (3) according to some criterion, *split or merge* intervals of continuous value, and (4) finally *stop* discretization. In the following we discuss these four steps in more detail.

3.2.1 Sorting

The continuous values for a feature are sorted in either a descending or an ascending order. Sorting can be computationally very expensive if care is not taken in implementing it with discretization. If sorting is done once and for all at the beginning of discretization, it is a *global* treatment and can be applied when the entire instance space is used for discretization. If sorting is done at each iteration of a process, it is a *local* treatment in which only a region of the entire instance space is considered for discretization.

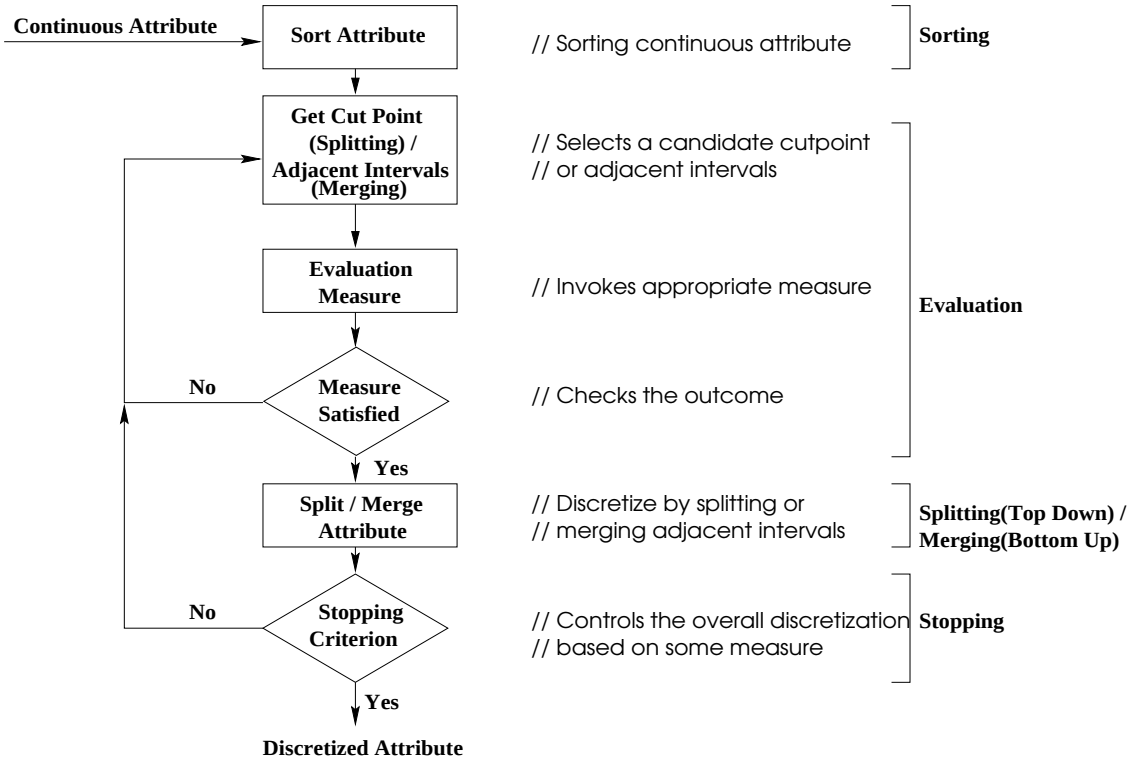

Figure 1: Discretization Process.

3.2.2 Choosing a cut-point

After sorting, the next step in the discretization process is to find the best cut-point to split a range of continuous values or the best pair of adjacent intervals to merge. One typical evaluation function is to determine the correlation of a split or a merge with the class label. There are numerous evaluation functions found in the literature such as entropy measures and statistical measures. More about these evaluation functions and their various applications will be discussed in the following sections.

3.2.3 Splitting/Merging

As we know, in a top-down approach, intervals are split while for a bottom-up approach intervals are merged. For splitting, it is required to evaluate cut-points and to choose the best one and split the range of continuous values into two partitions. Discretization continues with each part (increased by one) until a stopping criterion is satisfied. For merging, adjacent intervals are evaluated to find the best pair of intervals to merge in each iteration. Discretization continues with the reduced number (decreased by one) of intervals until the stopping criterion is satisfied.

3.2.4 Stopping Criteria

A stopping criterion specifies when to halt the discretization process. It is usually governed by a trade-off between arity and accuracy as the two are positively correlated. We may consider k to be an upper bound for the arity of the resulting discretization. In practice the upper bound k is set much less than N, assuming there is no repetition of continuous value for a feature. A stopping criterion can be very simple such as fixing the number of intervals at the beginning or a more complex one like evaluating a function. We describe different stopping criteria in the next section.

3.3 Comparison of discretization methods

Among the various discretized data obtained from various methods, which one is the best? This seemingly simple question cannot be easily dealt with in a simple answer. This is because comparison among various methods is a complex issue and it depends on the user's need in a particular application. It is complex because evaluation of various methods can be done in many ways. We list three important dimensions: (1) The total number of intervals - intuitively, the fewer the cut-points, the better the discretization result; but there is a limit imposed by the data representation. This leads to the next dimension. (2) The number of inconsistencies (inconsistency is defined later) caused by discretization - it should not be much larger than the number of inconsistencies of the original data before discretization. If the ultimate goal is to generate a classifier from the data, we should consider yet another perspective. (3) Predictive accuracy - how discretization helps improve

accuracy. In short, we need at least three dimensions: *simplicity, consistency,* and *accuracy.* Ideally, the best discretization result should score the highest in all the three dimensions. In reality, it may not be achievable, or necessary. To provide a balanced view of various discretization methods in terms of these measures is one of the objectives of this paper.

Simplicity is defined by the total number of cut-points. Accuracy can be obtained by running a classifier in a cross validation mode. Consistency is defined by having the least number of inconsistency counts which is calculated in three steps: (in the following description a pattern is a set of values for a feature set while an instance is a pattern with a class label) (1) two instances are considered inconsistent if they have the same attribute values but different class labels; for example, we have an inconsistency if there are two instances (0 1, a) and (0 1, $\bar{a}$) (where the class label is separated by a "," from the attribute values) - because of different classes a and $\bar{a}$. (2) the inconsistency count for a pattern is the number of times the pattern appears in the data minus the largest number of class label: for example, let us assume there are n instances that match the pattern, among them, c_1 instances belong to label_1, c_2 to label_2, and c_3 to label_3 where $c_1 + c_2 + c_3 = n$. If c_3 is the largest among the three, the inconsistency count is $(n - c_3)$. (3) the total inconsistency count is the sum of all the inconsistency counts for all possible patterns of a feature subset.

4 Discretization Framework

There are numerous discretization methods reported in the literature. These methods can be categorized along several dimensions as discussed earlier, namely, dynamic *vs.* static, local *vs.* global, splitting *vs.* merging, direct *vs.* incremental, and supervised *vs.* unsupervised. One can construct different combinations of these dimensions to group the methods. We wish to create a framework that is systematic and expandable, and capable of covering all existing methods. Each discretization method found in the literature discretizes a feature by either splitting an interval of continuous values or by merging adjacent intervals. Both splitting and merging categories can further be grouped as supervised or unsupervised depending on whether class information is used.

With these considerations in mind, we propose a hierarchical framework in Figure 2. We describe different discretization measures according to two approaches: splitting and merging (level 1). We then consider whether a method is supervised or unsupervised (level 2). We further group together methods that use similar discretization measures (level 3), e.g., binning and entropy. As is suggested in Figure 2, the supervised and unsupervised division determines different (non-overlapping) measures used. Hence this conceptually useful division will not be discussed in detail below. We will discuss the existing use of various measures under the categories of splitting and merging as shown in Table 1. We may find variations of these measures like Mantaras distance [4] which we categorize under entropy measure for similarity.

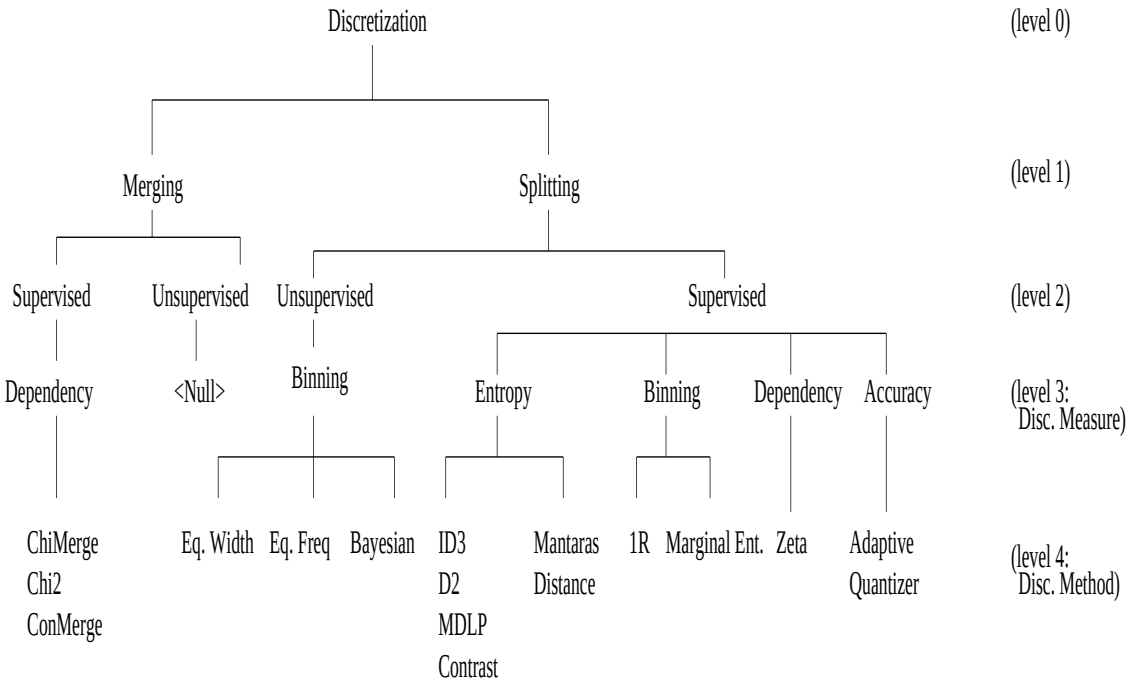

Figure 2: A Hierarchical Framework for Discretization Methods.

Measures	**Splitting**	**Merging**
binning	X	NA.
entropy	X	NA.
dependency	X	X
accuracy	X	NA.

Table 1: Measures applied to discretization categories

In the following two subsections, representative methods are chosen for in-depth discussion. Their related or derived measures are also briefly mentioned. For each discretization measure, we give: (1) the definition of the measure; (2) its use in discretization methods; (3) the stopping criteria used; and (4) its discretization results for the Iris data: cut-points for each attribute. The Iris data is used as an example to illustrate results of different discretization methods. The data is obtained from the UC Irvine data repository [1]. It contains 150 instances with four continuous features and three class labels. At the end of this section, for comparison purpose, we provide a table of the results for all the discretization measures (Table 15): numbers of inconsistencies and cut-points resulted from discretization of Iris.

4.1 Splitting methods

We start with a generalized algorithm for splitting discretization methods.

Splitting Algorithm

S = Sorted values of feature f

```
Splitting(S){
    if StoppingCriterion() == SATISFIED
        Return
    T = GetBestSplitPoint(S)
    S1 = GetLeftPart(S, T)
    S2 = GetRightPart(S, T)
    Splitting(S1)
    Splitting(S2)
}
```

The splitting algorithm above consists of all four steps in the discretization process, they are: (1) *sort* the feature values, (2) *search* for a suitable cut-point, (3) *split* the range of continuous values according to the cut-point, and (4) *stop* when a stopping criterion satisfies otherwise *go* to (2). Many splitting discretization measures are found in the literature: for example, binning [15], entropy [24, 3, 11, 29, 4], dependency [14], and accuracy [6].

4.1.1 Binning

It is the simplest method to discretize a continuous-valued attribute by creating a pre-specified number of bins. The bins can be created by *equal-width* and *equal-frequency*.

Feature	Cut Points Eq-Width	# Points	Cut Points Eq-Freq	# Points
F_1	5.2, 6.1, 7.0	3	5.1, 5.8, 6.4	3
F_2	2.6, 3.2, 3.8	3	2.8, 3.0, 3.3	3
F_3	1.9, 3.9, 5.4	3	1.6, 4.4, 5.1	3
F_4	0.6, 1.3, 1.9	3	0.3, 1.3, 1.8	3

Table 2: Cut-points determined by Equal-Width and Equal-Frequency

Equal width or frequency: In both methods, arity k is used to determine the number of bins. Each bin is associated with a distinct discrete value. In *equal-width*, the continuous range of a feature is evenly divided into intervals that have an equal-width and each interval represents a bin. In *equal-frequency*, an equal number of continuous values are placed in each bin.

The two methods are very simple but are sensitive to k. For equal-frequency, for instance, many occurrences of a continuous value could cause the occurrences to be assigned into different bins. This can be remedied by adjusting boundaries of neighboring bins so that duplicate values should belong to one bin only. Another problem is the presence of outliers that take extreme values. This can be overcome by removing the outliers using a threshold.

Stopping criterion: as the number of bins is fixed there is no need for any other stopping criterion.

Results: We discretized the Iris data using equal-width and equal-frequency methods with arity $k = 4$ and obtained different cut-points for each attribute as shown in Table 2. As values are not evenly distributed, in most cases, cut-points obtained by the two methods are different.

The above unsupervised methods do not consider the distribution of attribute values. Bayesian Discretization [17], on the other hand, considers the distribution of attribute values. This unsupervised method is based on clustering. The basic idea is to investigate all the possible clusters for a continuous attribute, i.e., assignments of the attribute values to the clusters. Each cluster is assumed to be normally distributed within its interval. This method uses the *K-means* algorithm [31] to cluster values of an attribute, where the user has to specify the number of clusters (K), thus the number of intervals, which is similar to the binning approach. Therefore, this method can also be categorized under binning.

1R: Binning methods mentioned above do not use any class information even if it is available. *1R* [15] is a supervised discretization method using binning. After sorting the continuous values, *1R* divides the range of continuous values into a number of disjoint intervals and adjusts the boundaries based on the class labels associated with the continuous values. Each interval should contain a minimum number of instances (6 by default) with the exception for the final interval which would

11	14	15	18	19	20	21	22	23	25	30	31	33	35	36
R	C	C	R	C	R	C	R	C	C	R	C	R	C	R
			C							C				R

Table 3: Cut-points searched by 1R

Feature	Cut Points	# Points
F_1	4.9, 5.5, 6.1, 6.6, 7.7, 7.9	6
F_2	2.7, 3.2, 4.2, 4.4	4
F_3	1.9, 6.9	2
F_4	0.6, 1.6, 2.5	3

Table 4: Cut-points determined by 1R

contain the remaining instances not yet grouped in any interval. The adjustment at the boundary does not allow one to terminate an interval if the next instance has the same class label as the majority class label seen until then in that interval. This can be made clearer with a simple example shown in Table 3. The first row in the example is the values of a feature after sorting while the second row stands for the class label (R or C). The first interval does not terminate after value 20 because the next instance with value 21 is of class C.

1R would form an interval of class C stretching from 11 to 21, another interval of class C from 22 to 35, and the last of class R including just 36. The two leftmost intervals would then be merged, as they predict the same class based on row 3 above. There are 6 misclassification after discretization.

Stopping criterion: The stopping criterion is indirectly specified by the minimum number of instances each interval should contain. The default value is 6.

Results: Discretization results of the Iris data set are shown in Table 4

Summary: Equal-width and equal-frequency are simple and easy to implement. This however comes with a price. First, arity k has to be specified beforehand. Because we usually do not know what a proper value k is, we need to resort to trial-and-error or specify a value randomly as we did for the Iris data. Second, even if the class information is available, these two measures cannot make use of it. 1R is one way to improve in this regard. It relies on the class information to overcome such problems that occur with equal-frequency when two instances with the same class label are placed in two different intervals. *Maximum marginal entropy* [9] is another way to improve equal-frequency

by using the class information when adjusting boundaries of neighboring bins.

For the Iris data, we provide the discretization results for equal-width, equal-frequency, and 1R. The three methods give different cut-points as shown in Table 2 and 4. For the Iris data with $k = 4$, equal-frequency is the best. Trial-and-error is usually adopted to find a good value for k.

4.1.2 Entropy Measure

Entropy is one of the most commonly used discretization measures in the literature. Shannon defines the entropy of a sample variable X in [26, 27] as:

$$H(X) = -\sum_x p_x \log p_x$$

where x represents a value of X and p_x its estimated probability of occurring. It is the average amount of information per event where the information of an event is defined as:

$$I(x) = -\log p_x.$$

Information is high for unlikely events and low otherwise. Hence, entropy H is the highest when each event is equi-probable, i.e., $p_{x_i} = p_{x_j}$ for all i, j; and it is the lowest when $p_x = 1$ for one event and 0 for all the other events.

ID3 type: ID3 [24] and C4.5 [25] are two popular algorithms for decision tree induction that use entropy measure. They construct an inductive decision tree by selecting a feature if its branching results in the overall minimum entropy at the next layer of the decision tree. A continuous feature has to be discretized to avoid creating too many branches for a node. ID3 employs a greedy search to find a potential cut-point within the existing range of continuous values using the following formula:

$$H = -p_{left} \sum_{j=1}^{m} p_{j,left} \log p_{j,left} - p_{right} \sum_{j=1}^{m} p_{j,right} \log p_{j,right}.$$

In this equation, m is the number of classes, p_{left} and p_{right} are probabilities that an instance is on the left or right side of a cut-point respectively. $p_{j,side}$ denotes the probability that an instance on the (left or right) *side* belongs to class j. The cut-point with the lowest entropy is chosen to split the range into two parts. Splitting continues with each part until a stopping criterion is satisfied. In fact, it binarizes a range at every split.

Stopping criterion: When every leaf node is pure (i.e, all instances in the node belong to one class), it stops. The condition can be relaxed based on the needs.

Results: Discretization results are not provided here for three reasons. One is that classification algorithms like ID3 and C4.5 do discretization (binarization) for continuous features under any circumstances. They do that at each branching node. Another reason is that the cut-points thus obtained are usually only good for the classification algorithm. We discuss this discretization method (binarization) here because it is a base for its many successors such as D2, Ent-MDLP. The third reason is that we will use C4.5 as a base for comparison in Section 5.

Feature	Cut Points	# Points

R	C	C	R	C	R	C	R	C	C	R	C	R	C	R

Table 6: Cut-points at the boundary

D2: This discretization method [3] applies entropy measure to find a potential cut-point to split a range of continuous values into two intervals. Unlike ID3 which binarizes a range of values while building a decision tree, D2 is a static method that discretizes the whole instance space. Instead of finding only one cut-point, it recursively binarizes ranges or subranges until a stopping criterion is met[1]. The discretized data is then used for building a classifier. A stopping criterion is essential to avoid over-splitting.

Stopping criterion: The stopping conditions used in D2 can be one of the following:

1. Stop if the number of instances to split is less than 14,
2. Stop if the number of intervals is more than 8,
3. Stop if the information gains on all cut-points are the same, or
4. Stop if all instances in the interval to be split belong to the same class.

One of the problems is that these stopping conditions are rather ad hoc. The next method (Ent-MDLP) provides a more principled way of determining when the recursive splitting should stop.

Results: For the Iris data, D2 gave the results in Table 5.

Ent-MDLP In [12], Fayyad and Irani propose that potential cut-points are those that form boundaries between classes after sorting the continuous feature values. Using the example data for 1R as shown in Table 6, we can see that the number of boundaries is 12 which is less than arity $k - 1$ (= 14) for cases without using any class information. Therefore, using the class information can increase the discretization efficiency as fewer potential cut-points need to be checked.

[1]Without a stopping criterion, it could reach a status that each distinct value is a cut-point.

Feature	Cut Points	# Points
F_1	5.4, 6.1	2
F_2	4.4	1
F_3	1.9, 4.9, 6.9	3
F_4	0.6, 1.6, 2.5	3

Table 7: Cut-points determined by Ent-MDLP

However, not all boundaries are needed to serve as cut-points for discretization. They employ an entropy minimization heuristic to select a candidate for the best cut-point of a feature. A minimum description length principle (MDLP) is used to determine if the candidate should be included as a best cut-point. If MDLP accepts the candidate, a new candidate will be searched and decided; if MDLP rejects the candidate, the discretization process terminates for that feature. A generalization of this measure is used for discretizing continuous features while learning Bayesian networks in [13].

Stopping criterion: MDLP is used as a stopping criterion. Hence, we name their method Ent-MDLP where Ent means entropy. It says that the partition induced by a cut-point for a set of instances is accepted if and only if the cost or length of the message required to send before partition is more than the cost or length of the message required to send after partition. A detailed account of how this is done can be found in [12].

Results: Ent-MDLP discretized the Iris data as shown in Table 7.

Mantaras distance: Cerquides and Mantaras [4] introduced a distance measure (*Mantaras Distance* [21]) to evaluate cut-points. Let us consider two partitions P_a and P_b on a range of continuous values, each containing n and m classes respectively. The Mantaras distance between the two partitions due to a single cut-point is given below. It chooses the cut-point that minimizes the distance.

$Dist(P_a, P_b) = \frac{I(P_a|P_b)+I(P_b|P_a)}{I(P_a \cap P_b)}$

Since $I(P_b|P_a) = I(P_b \cap P_a) - I(P_a)$,

$Dist(P_a, P_b) = 2 - \frac{I(P_a)+I(P_b)}{I(P_a \cap P_b)}$,

where

$I(P_a) = -\sum_{i=1}^{n} P_i \log_2 P_i$

$I(P_b) = -\sum_{j=1}^{m} P_j \log_2 P_j$

$I(P_a \cap P_b) = -\sum_{i=1}^{n} \sum_{j=1}^{m} P_{ij} \log_2 P_{ij}$

$P_i = \frac{|C_i|}{|N|}$

$|C_i|$ = total count of class i

$|N|$ = total number of instances

Feature	Cut Points	# Points
F_1	5.7, 7.9	2
F_2	3, 4.4	2
F_3	1.9, 4.4, 5.1, 6.9	4
F_4	0.6, 1.3, 1.8, 2.5	4

Table 8: Cut-points determined by Mantaras

$$P_{ij} = P_i \times P_j$$

Stopping criterion: It also uses the minimum description length principle discussed in Ent-MDLP as its stopping criterion to determine whether more cut-points should be introduced.

Results: Using this distance, we obtained results for the Iris data in Table 8.

Summary: ID3 type applies binarization to discretize continuous values while building a tree. D2 separates discretization from tree building and recursively binarizes ranges and/or subranges. Its problem is that there is no principled way to stop its recursive process of binarization. Ent-MDLP uses the minimum description length principle to determine when to stop discretization. It also suggests that potential cut-points are those that separate different class values.

Another work using entropy can be found in [29]. A *contrast* measure is introduced that uses the clustering concept to get the cut-point to induce a decision tree. The idea is to search for clusters that are contrasted as much as possible from the instance space proximity point of view. The cut-point for the maximum contrast is chosen. But the cut-point selected must be an informative one, i.e., it is not informative to select a cut-point that separates instances belonging to the same class. So, an entropy measure is proposed to select cut-points further. As it is mainly suggested in the context of tree building, we stop short of discussing it here and refer the interested reader to [29] for more details.

4.1.3 Dependency

Zeta: It is a measure of strength of association between a class and a feature. In [14], it is defined as the maximum accuracy achievable when each value of a feature *predicts* a different class value. We use a simple case to illustrate how Zeta is calculated. Assume that there is a continuous feature X with two values (X_1 and X_2) and two classes (C_1 and C_2) as shown in Table 9. The task is to find one cut-point (two intervals) at a time with the highest Z (zeta) value.

A modal class in interval i is determined as follows:

C_1 is the modal class, if $max(n_{1i}, n_{2i}) = n_{1i}$

Feature	X_1	X_2
C_1	n_{11}	n_{12}
C_2	n_{21}	n_{22}

Table 9: Zeta matrix

C_2 is the modal class, if $max(n_{1i}, n_{2i}) = n_{2i}$

where

i takes a value (1 or 2) if there are two intervals, and

n_{1i} is the number of instances in interval i that belong to C_1.

A Zeta value for a cut-point is:

$$Z = \sum_{i=1}^{k} n_{f(i),i}$$

where

k = number of pre-specified intervals (2 by default),

$f(i)$ = a class index that has the highest count of instances in interval i, and

$n_{f(i),i}$ = number of instances in interval i with class index $f(i)$ (modal class index).

For a feature with arity k, there could be $k-1$ potential cut-points. A cut-point with the highest Z value is selected if no neighboring pair of partitions predicts the same class (or two distinct class values should be predicted). This method continues binarizing subranges in the same spirit until the stopping criterion is met. A more complicated version of this method is when $k > 2$ which may incur an intractable discretization process [14]. Therefore, in practice k is set to 2.

Stopping criterion: The process stops when the specified number of intervals is reached for each continuous feature.

Results: The number of final intervals of a feature was specified as 4 (i.e., 3 cut-points). Zeta discretized the Iris data as shown in Table 10. Zeta obtained reasonable discretization results for this data. Clearly, with a different number of final intervals, the results will certainly change. We could also allow different features to have different final intervals if we have some prior knowledge about them.

4.1.4 Accuracy

Accuracy measure usually means the accuracy of a classifier. An example of using accuracy for discretization is *Adaptive Quantizer* [6]. It considers how well one attribute predicts the class at a time. For each attribute, its continuous range is split into two partitions either by equal-frequency

Feature	Cut Points	# Points
F_1	5.4, 6.1, 7.9	3
F_2	2.9, 3, 4.4	3
F_3	1.9, 4.7, 6.9	3
F_4	0.6, 1.6, 2.5	3

Table 10: Cut-points determined by Zeta

Feature	Cut Points	# Points
F_1	5.20, 6.10	2
F_2	2.60, 3.20	2
F_3	2.47, 3.95, 5.42	3
F_4	0.70, 1.30, 1.90	3

Table 11: Cut-points determined by Accuracy in Adaptive Quantizer

or by equal-width. The splitting is tested by running a classifier to see if the splitting helps improve accuracy. It continues binarizing subranges, and the cut-point that gives the minimum rate is selected. As it involves training a classifier, it is usually more time consuming than those without using a classifier.

Stopping criterion: For each attribute, the discretization process stops when there is no improvement in accuracy.

Results: We used C4.5 as the classifier to see the improvement while splitting attribute values using equal-width (Table 11).

The choice of a classifier depends on the user's preferences. However, as the classifier needs to be trained many times, it is necessary to choose one with a small time complexity. For example, C4.5 runs reasonably fast with time complexity $O(N \log N)$ where N is the number of instances.

4.2 Merging methods

We start here again with a generalized algorithm for discretization methods adopting the *merging* or bottom-up approach.

Merging Algorithm

S = Sorted values of feature f

Merging(S){

if StoppingCriterion() == SATISFIED

Return

T = *GetBestAdjacentIntervals(S)*

S = *MergeAdjacentIntervals(S, T)*

Merging(S)

}

The merging algorithm consists of the four important steps in the discretization process. They are: (1) sort the values, (2) find the best two neighboring intervals, (3) merge the pair into one interval, and (4) stop when the chosen stopping criterion is satisfied. Methods in this category [16, 19, 30] use the χ^2 statistic as one of the evaluation measures. Hence, we describe the measure first.

χ^2 measure: χ^2 is a statistical measure that conducts a significance test on the relationship between the values of a feature and a class. Kerber [16] argues that in an accurate discretization, the relative class frequencies should be fairly consistent within an interval (for otherwise the interval should be split to express this difference) but two adjacent intervals should not have similar relative class frequency (for otherwise the adjacent intervals should be merged into one). The χ^2 statistic determines the similarity of adjacent intervals based on some significance level. It tests the hypothesis that two adjacent intervals of a feature are independent of the class. If they are independent, they should be merged; otherwise they should remain separate. The formula for computing the χ^2 value is:

$$\chi^2 = \sum_{i=1}^{2} \sum_{j=1}^{p} \frac{(A_{ij} - E_{ij})^2}{E_{ij}}$$

where:

p = number of classes,

A_{ij} = number of distinct values in the ith interval, jth class,

R_i = number of examples in ith interval = $\sum_{j=1}^{p} A_{ij}$,

C_j = number of examples in jth class = $\sum_{i=1}^{m} A_{ij}$,

N = total number of examples = $\sum_{j=1}^{p} C_j$ and

E_{ij} = expected frequency of A_{ij} = $(R_i \times C_j)/N$.

ChiMerge: It is a supervised, bottom-up discretization procedure [16]. Initially each distinct value of the attribute is considered to be one interval. An χ^2 test is performed for every pair of adjacent intervals. Adjacent intervals with the least χ^2 value are merged together till the chosen stopping criterion is satisfied. A higher value of significance level for χ^2 test causes over discretization while a lower value causes under discretization. The recommended procedure is to set the significance level between 0.90 to 0.99 and have a *max-interval* parameter set to 10 or 15. This *max-interval*

Feature	Cut Points	# Points
F_1	4.3, 4.9, 5.0, 5.5, 5.8, 6.3, 7.1	7
F_2	2.0, 2.5, 2.9, 3.0, 3.4	5
F_3	1.0, 3.0, 4.5, 4.8, 5.0, 5.2	6
F_4	0.1, 1.0, 1.8	3

Table 12: Cut-points determined by ChiMerge

Feature	Cut Points	# Points
F_1	4.3, 4.9, 5.5, 5.8, 6.1, 7.1	6
F_2	2.0, 2.4, 2.9, 3.2, 3.4, 3.9	6
F_3	1.0, 1.9, 3.0, 3.6, 4.8, 5.2, 5.4	7
F_4	0.1, 1.0, 1.3, 1.8	4

Table 13: Cut-points determined by Chi2 (0% inconsistency)

parameter can be included to avoid the excessive number of intervals from being created.

Stopping criterion: The merging of adjacent intervals is repeated until χ^2 values of all pairs of adjacent intervals are smaller than a specified threshold value which is determined by a chosen significance level. The parameter *max-interval* is used to impose a constraint that the number of discretized intervals should be less than or equal to *max-interval*.

Results: Discretization results over all four features of the Iris data set are shown in Table 12.

Chi2: It is an automated version of *ChiMerge*. In *Chi2* [20], the statistical significance level changes to allow the merging of more and more adjacent intervals as long as the inconsistency criterion [19] is satisfied. By inconsistency, it means that two patterns match but belong to different categories. The algorithm not only discretizes the continuous data set but also selects a subset of relevant features. Like ChiMerge, the χ^2 statistic is used to discretize the continuous features until some inconsistencies are found in the data. By doing so, some features are removed as irrelevant, hence retaining a subset of relevant features that is consistent.

Stopping criterion: The merging continues until the inconsistency is no more than the set limit. The inconsistency limit is 0 by default.

Results: Discretization results over all four features of the Iris data set with 0 inconsistency are shown in Table 13.

One distinct feature of Chi2 is its capability to remove irrelevant attributes that do not help in classification. If we can tolerate some inconsistency, it is possible to merge the whole range of

Feature	Cut Points	# Points
F_1	Merged	0
F_2	Merged	0
F_3	1.0, 3.0, 4.8, 5.2	4
F_4	0.10, 1.00, 1.80	3

Table 14: Cut-points determined by Chi2 (3% inconsistency)

some attributes which are completely independent to the class. Table 14 shows that, by allowing 3% inconsistency, we could merge the first two attributes that are irrelevant.

A method very similar to Chi2 is *ConMerge* [30] which also uses the χ^2 statistic and the inconsistency measure. Instead of considering one attribute at a time, ConMerge chooses the lowest χ^2 value among the intervals of all continuous features. It requires more dynamic space.

Summary: ChiMerge is one of the first methods that moves away from a splitting approach. It specifically considers the relations between a feature and the class using the χ^2 statistic. The basic idea is that if a merge of two continuous values or two intervals does not affect the differentiation of class values, the merge should be accepted. χ^2 statistic allows some noise tolerance. The problem is how to set a proper threshold for each feature. Chi2 suggests an automatic way of tuning the threshold via the inconsistency measure. Another advantage of using Chi2 is to allow for some noise tolerance which leads to removal of irrelevant features. As seen in the case of allowing 3% inconsistency in the Iris data, the values of its first two features are merged into one value only.

4.3 Discussion

We have reviewed representative discretization methods under two categories: splitting and merging. The majority of methods are found in the splitting category. We used the Iris data as an example to show the different results obtained by various discretization methods without resorting to any classification algorithms in terms of *inconsistency* and *cut-points*. A summary of the results is shown in Table 15. An intuitive relation between the two evaluation measures (number of inconsistencies and number of cut-points) is that the more the cut-points, the fewer the inconsistencies. A closer look reveals that it is possible to have a middle ground that both counts are low. For example, Ent-MDLP incurred 3 inconsistencies and 9 cut-points and Chi2(3%) caused 4 inconsistencies and 7 cut-points for Iris. So we should aim to achieve low values in both numbers (inconsistencies and cut-points). We indeed observe that some did better than others for the Iris data: Ent-MDLP was the best in the category of splitting; Chi2 in the category of merging. Chi2 also showed that a

Method	# Inconsistency	# Point
Equal-width	10	12
Equal-freq	6	12
1R	7	15
D2	1	26
Ent-MDLP	3	9
Mantaras	8	12
Zeta	3	12
Accuracy	10	10
ChiMerge	4	21
Chi2	0	23
Chi2(3%)	4	7

Table 15: Discretization results of Iris in numbers of inconsistencies and cut-points.

trade-off between the two measures is possible by allowing some percentage of inconsistency. In addition to discretization, Chi2 can also remove features with some level of inconsistency as seen in Table 14.

The proposed framework has served one purpose so far: it helps us organize many discretization methods so that we can describe the methods in groups and observe their performance. Its other aspects are:

1. providing an overall picture of various methods and indicating their relations among them;
2. suggesting what is missing according to this framework and what methods are more similar than others; and
3. offering a starting point to think of new measures or methods; in other words, we hope that this framework makes the design of new methods easier.

If we reorganize the discretization methods according to the five different dimensions reviewed in Section 2, namely, global *vs.* local, supervised *vs.* unsupervised, direct *vs.* incremental, splitting *vs.* merging, and static *vs.* dynamic, we obtain another type of groupings in a multi-dimensional view as seen in Table 16.

Methods	Global/ Local	Supervised/ Unsupervised	Direct/ Incremental	Splitting/ Merging	Static/ Dynamic
Equal-width	Global	Unsupervised	Direct	Splitting	Static
Equal-frequency	Global	Unsupervised	Direct	Splitting	Static
1R	Global	Supervised	Direct	Splitting	Static
D2	Local	Supervised	Incremental	Splitting	Static
Ent-MDLP	Local	Supervised	Incremental	Splitting	Static
Mantaras	Local	Supervised	Incremental	Splitting	Static
ID3	Local	Supervised	Incremental	Splitting	Dynamic
Zeta	Global	Supervised	Direct	Splitting	Static
Accuracy	Global	Supervised	Direct	Splitting	Static
ChiMerge	Global	Supervised	Incremental	Merging	Static
Chi2	Global	Supervised	Incremental	Merging	Static
ConMerge	Global	Supervised	Incremental	Merging	Static

Table 16: Representative discretization methods in multiple dimensions. Double horizontal lines separate different combinations.

5 Experiments and Analysis

Using the Iris data, we clearly see that discretization simplifies data without sacrificing the data consistency much (only a few inconsistencies occur after discretization). We are now ready to evaluate the ultimate objective of discretization - whether discretization helps improve the performance of learning and understanding of the learning result. The improvement can be measured in three aspects through before/after discretization comparison: (1) accuracy, (2) time for discretization and for learning, and (3) understandability of the learning result. Thus, we need a classification learning algorithm. A critical constraint for choosing such a learning algorithm is that it should be able to run with both data types, i.e., continuous as well as discrete. Not every learning algorithm can do so. Naive Bayes Classifier [8, 18], as an example, can only run on discrete data. C4.5 [25] is chosen for experiments because it can handle both data types and it is conveniently available and widely used so that a reader can easily repeat the experiments here. Furthermore, C4.5 has become a de facto standard for comparison in machine learning and can run without any parameter setting[2]. We have re-implemented the discretization methods used in the experiments based on the descriptions of the published papers. *The programs of these discretization algorithms are available through ftp or web access free of charge upon request.* We will examine the effect of discretization on C4.5 through comparisons before/after discretization. Before doing so, we outline the specific meaning of each aspect of evaluation.

- Accuracy - we wish to see if discretization would result in the decrease or increase of accuracy. The usual 10-fold cross validation procedure is used.
- Time for discretization - we wish to see if a discretization method that takes more time would result in a better accuracy.
- Time for learning with different data types of the same data - with which data types the learning requires more time to complete.
- Understandability - the learning result of C4.5 is a decision tree. This aspect is indirectly measured through the number of nodes in a tree.

5.1 Experiment set-up

Twelve data sets are selected from the UC Irvine machine learning data repository [1] with all numeric features and varying data sizes. A summary of the data sets can be found in Table 17. A total of 8 discretization methods excluding ID3 type, Equal-width, Accuracy, and ConMerge (see Table 16) are chosen to compare. The Accuracy method takes too long time as every selection of a cut-point invokes a decision tree learning. The ID3 type is used as the base for comparison, as we

[2]We wish to minimize any other factors that can possibly influence the results of before and after discretization.

	Data	Total#Instances	#Features
1	Australian	690	14
2	Breast	699	9

Table 17: Summary of data sets.

use C4.5 (an improved version of ID3) to provide the figures of performance before discretization. Equal-width is similar to Equal-Freq. We choose the latter based on our experience gained in Section 4. ConMerge is a variant of Chi2.

Each experiment is conducted as follows:

- for each data set
  - test each discretization method by 10-fold cross validation of C4.5
    1. take every 9/10 of the data in each round (10 in total)
    2. run a discretization method to get cut-points, measure the time needed
    3. use these cut-points to discretize the remaining 1/10 data
    4. use the above 9/10 data for *training* and the remaining data for *testing*
  - report the average error rate and time of C4.5.

For the results without discretization, we skip steps 2 and 3 in the above procedure.

5.2 Results and analysis

C4.5 results are shown in Tables 18 and 19. Each result consists of the mean and deviation of the reported error rates of the 10-fold cross validation. The results of C4.5 without discretization are listed in the column "Continuous" in Tables 18 for comparison with the results after applying various

discretization methods. The results are grouped in terms of the characteristics of discretization methods for easy comparison. The averages in the last rows of Tables 18 and 19 give an indication as to how the discretization methods affect predictive accuracy. Most discretization methods do not significantly increase error rates. In the meantime, we also need to look at other dimensions for performance evaluation.

Table 20 reports the time taken by each discretization method. It is clear that each method takes varying amount of time. This only serves as an indication because of the flexibility shown in each method's stopping criterion. What is interesting to us is whether more time spent on discretization for a method, will mean a lower error rate for C4.5. Figure 3 suggests that there is such a relation. A similar finding is reported in [14]. The difference is that we measure the time taken only by the discretization step while they measure the time taken by discretization and by classification. The values in Figure 3 are averaged over all data sets and taken from the last rows of Tables 18, 19, and 20. The idea is to see if there is any trade off between the error rate of C4.5 on discretized data *vs.* the speed of a discretization method. The three methods that spent the least amount of time produced the highest average error rates on the data sets. As seen in Figure 3, in general, the

extra amount of time is worthwhile for the sake of low error rates, except for the case of Mantaras. Other things being equal, a user may choose a method that gives a lower error rate.

How does discretization affect the learning of a decision tree? As we suggested earlier, in addition to error rates, we can check the learning time of C4.5 on the discretized data and the number of nodes of a resulted decision tree with respect to the one built from the original data. Tables 21 and 22 summarize the experimental results in these two aspects. The learning time is reduced almost by half as compared to that on learning from continuous data. All discretization methods contribute to time saving in learning. This is consistent with the theoretical findings in [28, 23] that numeric data typically requires repetitive sorting, so it needs a $\log N$ factor at each node for C4.5; but not so for discrete data. In Table 22, the average number of nodes in a decision tree for all the data sets is also reduced. This concludes that discretization helps summarizing the data.

In order to facilitate our understanding of different discretization methods in their groups, we show the eight discretization methods in Figures 4 (a), (b) and (c) using the result of C4.5 without discretization as the base case. A negative difference means an improvement in accuracy. Several points can be noted from Figure 4: (1) Similar discretization methods show the same trend of increase or decrease of error rates for the 12 data sets. Eq-Freq and 1R, D2 and Ent-MDLP,

Average	46	39	43	36	38	40	33	46	42

Table 22: Numbers of nodes in trees induced by C4.5 before and after discretization.

ChiMerge and Chi2 behave similarly in pairs with the exception that Mantaras and Zeta have their distinctive behaviors. (2) Some methods change drastically (exceeding 7% difference) - Eq-Freq, 1R, Mantaras, and Zeta. One changes mildly (within 7% difference) - Chi2. Some change a little (within 5% difference) - D2 and Ent-MDLP, ChiMerge. In this regard, D2 is the most stable with a difference less than 2% for all data sets. (3) No one discretization method can ensure a negative difference for all data sets. Combining the findings in Figures 3 and 4, we recommend D2, Ent-MDLP for a splitting approach and ChiMerge and Chi2 for a merging approach.

Data Set	#MethodBetter
1. Australian	7/8
2. Breast	0/8
3. Glass	0/8
4. Heart	7/8
5. Vehicle	0/8
6. Iris	2/8
7. Wine	0/8
8. Pima	4/8

Table 23: Summary of results for C4.5: Table (a) shows the number of methods for each data set for which C4.5 performs better than without discretization. Table (b) shows the number of data sets for each method for which C4.5 performs better than without discretization.

Table 23 shows the summary of results across the data sets and across the discretization methods. As per Table 23, in 37 out of a total of 96 cases (12 'data sets' times 8 'methods') the error rate was less than or equal to that of C4.5 without discretization. The Ent-MDLP method gave the best results for error rate (7 out of 12 data sets) whereas Equal-freq and Zeta methods gave the worst results (2 out of 12 data sets). Similarly among the data sets, PageBlock, Australian and Heart showed the most improvement after discretization (8 out of 8 for PageBlock and 7 out of 8 methods for Australian and Heart) while Breast, Glass, Vehicle, and Wine showed the least improvement (0

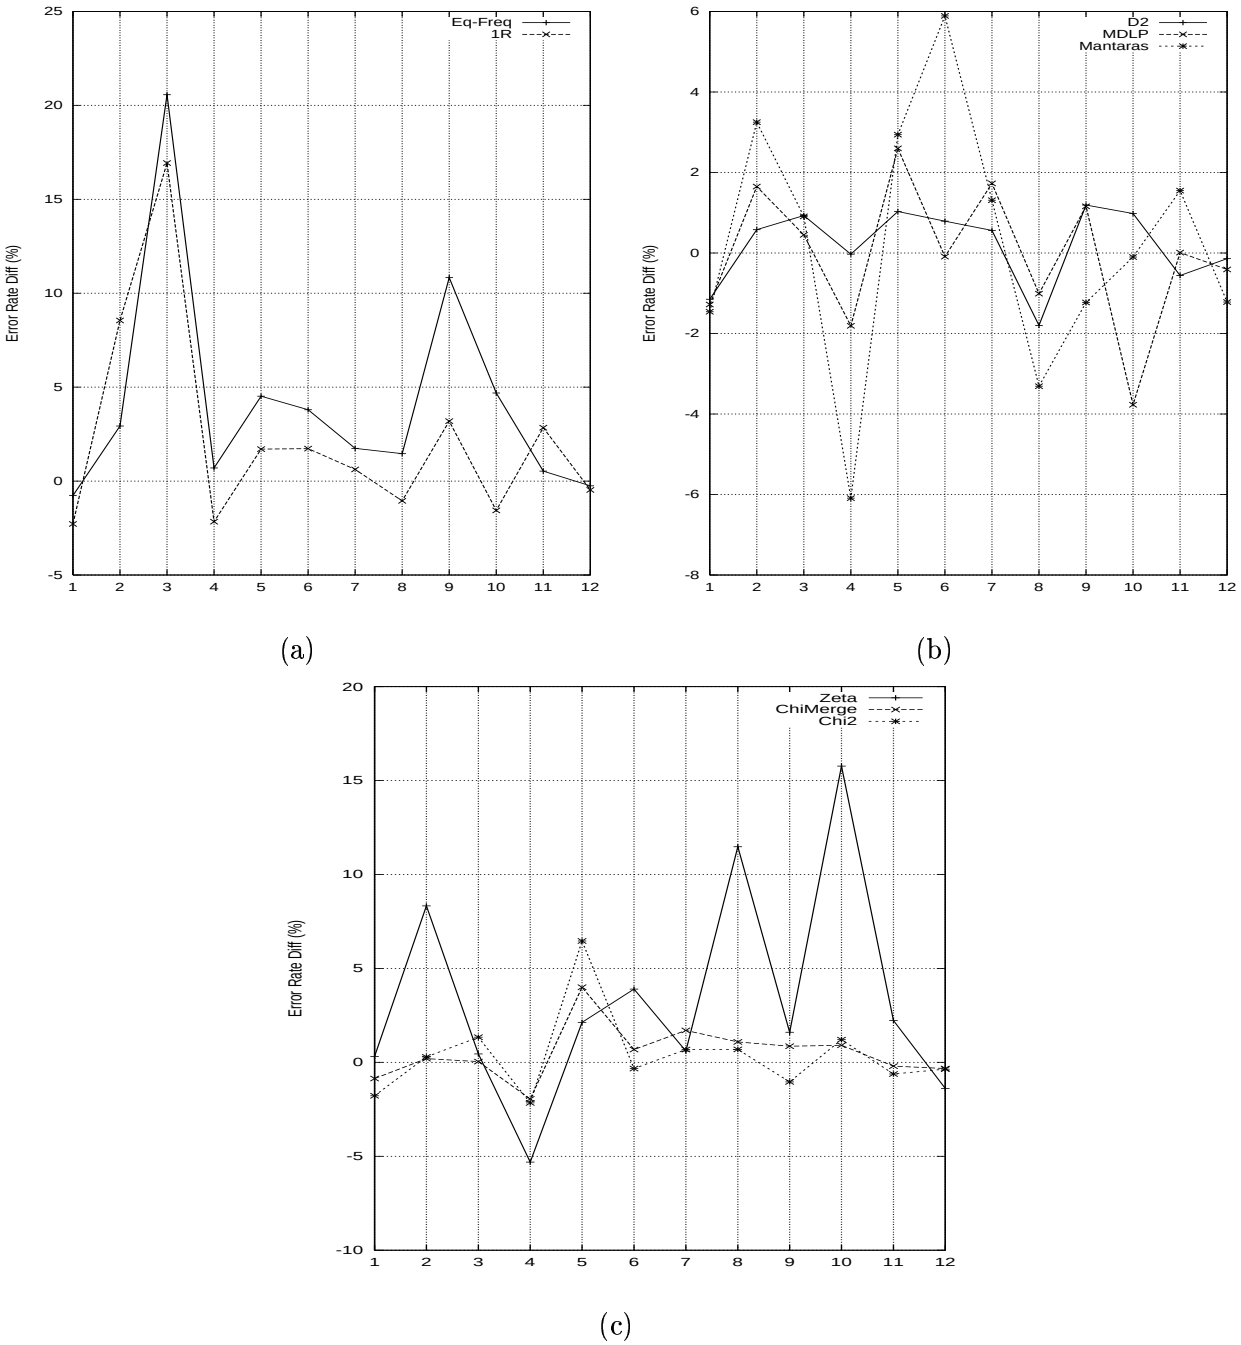

Figure 4: Error rates of C4.5 before and after discretization. The error rates are shown relative to the classification error before discretization. The numbers on the axis of data sets are given as indexes in Table 17. The results are summarized in Table 23.

out of 8 methods).

6 Conclusion and Future Work

We present a survey of discretization methods and discuss various dimensions in which discretization methods can be categorized. A typical discretization process is described after introducing some common terms and notations. We then propose a hierarchical framework for discretization methods by considering several important dimensions. Representative methods are given from the perspective of splitting and merging and are further discussed according to the measures used. We discuss each method and its stopping criterion, and present the discretization results for the Iris data, as an illustrative working example, in terms of number of inconsistencies and number of cut-points. Experiments for chosen discretization methods have been conducted on 12 data sets with C4.5. The performance of discretization methods is evaluated with time for discretization and time for learning, C4.5 error rates before and after discretization, and number of nodes in a decision tree. It is observed that in general, more time on discretization leads to a better accuracy for C4.5. Our findings in Sections 4 and 5 are quite consistent as both identify Ent-MDLP as the first choice.

However, choosing a suitable discretization method is generally a complex matter, and largely depends on the user's need for discretization, as well as on the kind of data to be discretized. If the data does not have any class information, only unsupervised discretization methods can be applied. When class information is available, a supervised method should be employed. Do we wish to remove redundant/irrelevant features? If so, Chi2 is a choice. If we need to incorporate discretization into a learning process, dynamic discretization methods such as ID3, Contrast should be considered. To reiterate, if we simply want to discretize data, other things being equal, Ent-MDLP is the first choice to consider.

The reader may notice that the discretization methods discussed so far implicitly assumes feature independence. Therefore, all these methods are univariate methods for the sake of efficiency. As we know, the assumption may not be valid in practice. When we discretize, we may need to consider multiple features at a time, the so-called multivariate discretization. Doing so would inevitably increase time complexity of discretization. Using the inconsistency measure in Chi2 is one effort towards taking into account the joint contribution of features. With the availability of more powerful parallel computers or computer clusters, we may investigate the possibility of using these computers for multivariate discretization. Parallel discretization algorithms are very useful when a large number of continuous features should be quantized. With the feature independence assumption, it seems possible to extend the methods to parallelized versions.

Sometimes, a data set consists of various types of features. In Chi2, concepts of over/under discretization are suggested to account for mixed types of features [20]. Again, mixed types of features

would not cause a problem if the feature independence assumption is acceptable. It is obviously not the case in the context of multivariate discretization. Noise handling is another important issue of discretization in practice. To allow a certain degree of tolerance through thresholding is a common practice for noise handling in the methods discussed here. Chi2 suggests the use of the number of inconsistencies as a way to handle one type of noise. However, it requires prior knowledge about noise. In short, this survey does not conclude discretization research. Instead, it signifies the start of a new phase of discretization research. As we can see, while a lot of work has been done, there are still many issues that remain unsolved, and new methods are needed to address these issues. We hope that this paper will provide a reference point to facilitate researchers and practitioners to embark on further research, development and applications.

Acknowledgment

The constructive and insightful comments provided by the anonymous reviewers have helped us to substantially improve the content and presentation of the paper.

The authors wish to thank Jian Shu for his help in implementing some of the discretization methods discussed in the paper and making the present form of experiments possible.
